**Abstract:** ATHAPASCAN was an macro data-flow application programming interface (API) for asynchronous parallel programming. The API permits to define the concurrency between computational tasks which make synchronization from their accesses to objects into a global distributed memory. The parallelism is explicit and functional, the detection of the synchronizations is implicit. The semantic is sequential and a ATHAPASCAN's program is independent from the target parallel architecture (cluster or grid). The execution of program relies on an interpretation step that builds a macro data-flow graph. The graph is direct and acyclic (DAG) and it encodes the computation and the data dependencies (read and write). It is used by the runtime support and the scheduling algorithm to compute a schedule of tasks and a mapping of data onto the architecture. The implantation is based on using light weight process (thread) and one-side communication (active message). This report presents the C++ library of the API of ATHAPASCAN.

**Key-words:** parallel programming, macro data flow, scheduling, cluster and grid computing

# **ATHAPASCAN : une Interface pour la Programmation Parallèle Asynchrone**

## **Manuel de l'utilisateur**

**Résumé :** ATHAPASCAN est une interface de type macro data-flow pour la programmation parallèle asynchrone. Cette interface permet la description du parallélisme entre tâches de calcul qui se synchronisent sur des accès à des objets à travers une mémoire globale distribuée. Le parallélisme est explicite de type fonctionnel, la détection des synchronisations est implicite. La sémantique est de type séquentielle et un programme écrit en ATHAPASCAN est indépendant de l'architecture parallèle (grappe ou grille). L'exécution est basée sur une interprétation du programme qui permet la construction d'un graphe macro data-flow. Ce graphe, orienté et sans cycle, décrit les calculs et les dépendances de données (lecture et écriture); il est utilisé par le support d'exécution pour contrôler l'ordonnancement des tâches de calcul et le placement des données sur les ressources de l'architecture. L'implantation repose l'utilisation de threads et de communications unidirectionnelles (messages actifs). Ce rapport présente l'utilisation de l'API d'ATHAPASCAN en tant que bibliothèque C++.

**Mots-clés :** programmation parallèle, macro data flow, ordonnancement, grappe et grille de calcul

## 1 Information and contacts

The ATHAPASCAN project is still under development. We do our best to produce as good documentation and software as possible. Please inform us of any bug, malfunction, question, or comment that may arise.

More information about ATHAPASCAN and the APACHE project can be found online at:

`http://www-apache.imag.fr`.

The user can subscribes to the following mailing-lists:

- `http://listes.imag.fr/wws/info/id\_a1\_hotline`: to have help from the ATHAPASCAN's group about installation or programming pitfalls or bug report.
- `http://listes.imag.fr/wws/info/id\_a1\_devel`: to reach the developers of ATHAPASCAN's group about implementation details (questions, remarks, design, ...).

The authors thank all the people who has worked on this project:

## Contents

## 2 Introduction

ATHAPASCAN-1 is the C++ application programming interface of ATHAPASCAN. It is a library designed for the programming of parallel applications.

### 2.1 About ATHAPASCAN

ATHAPASCAN is build on a multi-layered structure:

1. Athapascan-0 is the communication layer based upon MPI and POSIX threads; the extension independent from the transport library is called INUKTITUT;
2. ATHAPASCAN-1 is the user-end API;
3. ATHAPASCAN also contains visualization tools for debugging purposes.

ATHAPASCAN is a **“high level”** interface in the sense that no reference is made to the execution support. The synchronization, communication, and scheduling of operations are fully controlled by the software.

ATHAPASCAN is an **explicit parallelism language**: the programmer indicates the parallelism of the algorithm through ATHAPASCAN’s two, easy-to-learn template functions, `Fork` and `Shared`. The programming semantics are similar to those of a sequential execution in that each “read” executed in parallel returns the value it would have returned had the “read” been executed sequentially.

ATHAPASCAN is implemented by an easy-to-use C++ interface. Therefore any code written in either the C or C++ languages can be directly recycled in ATHAPASCAN.

The ATHAPASCAN interface provides a **data-flow language**. The program execution is data driven and determined by the availability of the shared data, according to the access made. In other words, a task requesting a read access on shared data will wait until the previous task processing a write operation to this data has ended.

ATHAPASCAN is **portable and efficient**. The portability is inherited from the Athapascan-0 communication layer of the environment, which may be installed on all platforms where a POSIX threads kernel and a MPI communication library have been configured.

The efficiency with which ATHAPASCAN runs has been both tested and theoretically proven. The ATHAPASCAN programming interface is related to a cost model that enables an easy evaluation of the cost of a program in terms of work (number of operations performed), depth (minimal parallel time) and communication volume (maximum number of accesses to remote data). The execution time on a machine can be related to these costs [?].

ATHAPASCAN has been developed in such a way that one does not have to worry about specific machine architecture or optimization of load balancing between processors. Therefore, it is much simpler (and faster) to use ATHAPASCAN to write parallel applications than it would be to use a more “low level” library such as MPI.

### 2.2 Reading this Document

This document is a tutorial designed to teach one how to use ATHAPASCAN’s API. Its main goal is not to explain the way ATHAPASCAN is built.

If new to ATHAPASCAN, it is recommended to read all of the remaining text. However, if the goal is to immediately begin writing programs with ATHAPASCAN, feel free to skip the next two chapters. They simply provide an overview of:

- how to install ATHAPASCAN’s librairies, include files, and scripts (Chapter ??),
- how to test the installation performed (Chapter ??),
- the API (Chapter ??).

The other sections will delve deeper into ATHAPASCAN’s API, so that the user can benefit from all of its functionalities. They explain:

- the concepts of “tasks” and “shared memory” (Chapters ?? and ??, respectively);

- how to write the code of desired tasks (Chapter ??);
- how to make shared types communicable to other processors (Chapter ??);
- which type of access right to shared memory should be used (Section ??);
- how to design parallel programs through complex examples (Chapter ??);
- how to select the proper scheduling algorithm for specific programs (Appendix ??);
- how to debug programs using special debugging and visualizing tools (Appendix ??).

### 3 Installation of Athapascan-1 version 2.0 Beta

ATHAPASCAN is easy to install. This chapter only covers the installation of Athapascan-1 version 2.0 Beta on a UNIX system.

The latest releases of ATHAPASCAN software are available for download on APACHE's web-site:

<http://www-apache.imag.fr/software/ath1/archives/>.

#### 3.1 Installation of Inuktitut and Athapascan

The entire installation is based upon the couple, `configure/makefile`. There is a **makefile** in the top level of the both the Inuktitut (the execution support) and the Athapascan-JIT-1.3 folders that provide sound settings for the installation. Modify the settings at the beginning of the file in order to finalize the installation to the desired folder.

Next execute:

```
make config
```

In order to define certain variables at the time of compilation, use the command `make "CXXGLAGS=..."` in each of the folders, Inuktitut and Athapascan-JIT-1.3.

## 4 Getting Started (API)

This chapter presents an overview of ATHAPASCAN's API and demonstrates how to build ATHAPASCAN programs through simple examples.

NB: The source codes of the examples presented in this tutorial are available online on our web-site.

### 4.1 Overview of ATHAPASCAN

#### 4.1.1 Starting an ATHAPASCAN Program

The execution of an ATHAPASCAN program is handled by a "community." A community restructures a group of nodes (Inuktitut processes) so that they can be distributed to the different parallel machines. Therefore, prior to the declaration of any ATHAPASCAN object or task, a community must be created. Currently, this community only contains the group of nodes defined at the start of the application.

A community is created by executing the instruction:

```
a1::Community com = a1::System::create_initial_community( argc, argv );
```

Once the community has been created the following methods will be available:

- `com.is_leader()` : that returns true on one and only one of the nodes (processes) of that community
- `com.sync()` : that waits for all of the created tasks to finish executing on the collection of nodes before execution on this node resumes.
- `com.leave()` : indicates to the current process to leave that community

Usually a community is defined in the `main` method of the program. To ensure a proper creation of a community, it is also necessary to catch any exceptions that might be thrown by the initialization procedures. The skeleton

of an ATHAPASCAN program should resemble the following block of code.

```
int doit (int argc, char** argv)
{
    ...
    return 0;
}

int main(int argc, char** argv)
{
    try {
        a1::Community com =
            a1::System::create_initial_community(argc, argv);
        std::cout << "count argc" << argc << std::endl;
        if (argc != N) {
            for (int i=0; i<argc; ++i)
                std::cout << argv[i] << std::endl;
            std::cout << "usage: " << argv[0] << "PROPER USAGE " << std::endl;
            return 0;
        }

        doit( argc, argv );
        com.leave();
    }
    catch (const a1::InvalidArgument& E) {
        std::cout << "Catch invalid arg" << std::endl;
    }
    catch (const a1::BadAlloc& E) {
        std::cout << "Catch bad alloc" << std::endl;
    }
    catch (const a1::Exception& E) {
        std::cout << "Catch : ";
        E.print(std::cout);
        std::cout << std::endl;
    }
    catch (...) {
        std::cout << "Catch unknown exception: " << std::endl;
    }

    return 0;
}
```

The function `doit` should contain the code to be executed in parallel. The function `main` in this case simply creates the community, executes `doit`, and catches any exceptions thrown. The variable `N` represents the constant number of inputs needed to run the program (when coding this line, replace `N` with the desired number). If there are not enough inputs specified at run-time, the program should terminate and output a message describing the proper usage of the program. It is necessary to execute the `com.leave()` function to facilitate the termination of the ATHAPASCAN application. Calling `doit` from `main` simplifies the code, making it easier to read.

**Note:** From this point on, all examples contained in this document will define a method `doit`. It is to be assumed that the program is executed with a `main`, as defined above. That is to say that the `main` method will not be shown in the examples.

#### 4.1.2 Fork

Fork is the keyword used by ATHAPASCAN to define tasks that are to be parallelized. To Fork a task, one must:

- **write the code to be parallelized** (overload the “operator()” of the class to be Forked);  
syntax:

```
struct my_Task {
    operator()( formal parameters )
        task body
    }
};
```

- **invoke the task** (call to the method “Fork”);  
syntax:

```
a1::Fork <my_task>() ( effective parameters );
```

Example:

```
struct PrintHello {
    void operator()(int id) {
        printf("Hello world from task number % n", id);
    }
};

int doit( int argc, char** argv) {
    ...
    a1::Fork < PrintHello > ()(i);
    ...
    return 0;
}

int main( int argc, char**argv )
{
    // MAIN METHOD AS PREVIOUSLY DEFINED IN API CHAPTER

    return 0;
}
```

NB: All the formal parameters must be made communicable (Cf. Chapter ??).

- **parameters:** A task parameter can be:
  1. a regular object or variable  
ex: a1::Fork<myTask> ()(class T), with T communicable).
  2. a Shared data that can be used by different tasks  
ex: a1::Fork< myTask > () (a1::Shared\_r< myClass > T), with myClass communicable.  
A Shared data can have different access rights (Cf. Chapter ??).

NB: Shared data must be initialized (A runtime error occurs if this is not done).

Example:

```

struct print_A_Shared {
    void operator()(a1::Shared_r<int> T) {
        printf("The Shared data parameter has the value: % d", T.read());
    }
} ;

int doit ( int argc, char** argv) {
    ...
    a1::Shared<int> myShared(new int(10)) ;
    a1::Fork < print_A_Shared > ()(myShared) ;
    ...
    return 0;
}

int main( int argc, char**argv )
{
    // MAIN METHOD AS PREVIOUSLY DEFINED IN API CHAPTER

    return 0;
}

```

- **communicable type:**

Only serialized classes can be communicated. The standard classes and types (short, unsigned short, int, unsigned int, long, unsigned long, char, unsigned char, float, double, long double, char\*, void\*, Standard container classes of the STL) are already communicable by default. User defined classes may be complex. It is therefore necessary to explain to the library how these classes should be serialized. These classes and types have to be explicitly made communicable by implementing specific class methods (Cf. Chapter ??).

### 4.1.3 Shared Object

A task can access only the objects it has declared or received as effective parameters. The access to a shared object can be:

- **read only** (a1::Shared\_r<class T>),
- **write only** (a1::Shared\_w<class T>),
- **cumulative write** (a1::Shared\_cw<class F, class T>),
- **read/write** (a1::Shared\_r\_w<class T>).

NB1: A shared object can implement only communicable classes.

NB2: A pointer given as parameter has to be considered as lost by the programmer (all further access through this pointer is invalid).

#### Declaration :

- **a1::Shared< T > x;** the reference x must be initialized before use.
- **a1::Shared< T > x( 0 );** the reference x can be used but no initial data is associated with it.
- **a1::Shared< T > x( new T( ... ) );** the reference x can be used and possesses an initial value.

NB: Be aware that non-initialized shared data is a common programming error that gives no compile-time warning.

## Access Rights and Methods :

Each task specifies as a parameter the shared data objects that will be accessed during its execution and which type of access will be performed on them.

According to the requested access right, tasks should use this methods:

- read only access (`a1::Shared_r<T> x`):

```
use x.read()
prototype: const T& read() const;
```

- write only access (`a1::Shared_w<T> x`):

```
use x.write(p)
prototype: void write(T*);
```

NB: Deallocation is made by ATHAPASCAN .

- read write access (`a1::Shared_r_w<T> x`):

```
use x.write(p) or x.access()
prototype: void write(T*);
prototype: T& access();
```

- accumulation write access (`a1::Shared_cw<F,T> x`):

```
use x.cumul(v)
prototype: void cumul( const T& );
```

NB: The call `x.cumul( v )` accumulates `v` into the shared data according to the accumulation function `F`. A copy of `v` may be made during the first accumulation if the data present is not yet valid.

Example:

```

struct add {
    void operator()(int& a, const int& b) const {
        a+=b;
    }
};

struct addToShared {
    void operator()(a1::Shared_cw<add, int> T, int i ) {
        T.cumul(i);
    }
} ;

int doit( int argc, char** argv) {
    ...
    a1::Shared<int> myShared(new int(10)) ;
    a1::Fork < addToShared > ()(myShared, 5) ;
    ...
    return 0;
}

int main( int argc, char**argv )
{
    // MAIN METHOD AS PREVIOUSLY DEFINED IN API CHAPTER

    return 0;
}

```

### Conversion Rules :

Due to the several types of `Shared` data with specific reading and writing capabilities, there are restrictions on how `Shared` objects may be passed with respect to their access right. Since this material is rather extensive, Chapter ?? page ?? is devoted to the study of the `Shared` object and thus not covered in this chapter.

### Adding thread information :

Some scheduling policies benefit from thread information. ATHAPASCAN uses four variables to determine the best method of execution. Each datum has a default value but a better scheduling may be obtained if the programmer assigns significant values. The variable information retained is:

- The **cost** of the thread (a C++ double).
- The **locality** of the thread (a C++ int).
- The **priority** of the thread (a C++ int). Low values traduce higher priorities.
- An **extra** attribute (a C++ double) that represents whatever the scheduler wants it to represent.

This information is given at the thread creation:

```
a1::Fork<user_task> (SchedAttributes( infos )) (<parameters>);
```

Where `<infos>` represent the list of the four possible thread attributes. Here is an example of how to use the scheduling attributes:

```
a1::Fork<user_task> (SchedAttributes( prio, cost, loc, extra )) (<parameters>);
```

Note that if both a specific scheduler and some information are given, the order in which the variables are passed is not important:

```

a1::Fork<user_task> (SchedAttributes( prio, cost, loc, extra ), sched_group ) (<parameters>);
a1::Fork<user_task> (sched_group, SchedAttributes( prio, cost, loc, extra )) (<parameters>);

```

#### 4.1.4 System Information

It is possible to get the following runtime information:

- `a1_system::node_count()` returns the number of nodes
- `a1_system::self_node()` returns the node identification number on which the function is invoked, an integer from 0 to `a1_system::node_count()-1`
- `a1_system::thread_count()` returns the number of a0 threads dedicated to a thread's execution on the virtual processor
- `a1_system::self_thread()` returns the a0 thread identification number that hosts the execution of the thread, an integer from 0 to `a1_system::thread_count()-1`

#### 4.1.5 Compilation and Execution

The compilation of an ATHAPASCAN program is performed by the `make` command using the **Makefile** created upon installaion. Be sure to modify the **Makefile** as needed, to personalize the folders containing the include and library files.

An ATHAPASCAN program is executed in the same manner as one would execute any other program from the command line. For example a common execution may resemble: `sh ./program_name <inputs>`

## 4.2 Basic Examples

This section is a brief tutorial of how to build simple ATHAPASCAN programs; it proceeds by teaching through examples. The two examples presented in the section are `getInfoTask.cpp` (a program that demonstrates how to retrieve system information), and `Fibonacci.cpp` (a program which computes the Fibonacci number of a given input). More thourough examples are offered in Chapter ?? but use concepts that have not been discussed thus far.

### 4.2.1 Simple Example 1: “getInfoTask.cpp” (1 Fork - 0 Shared)

Let's start with an example implementing the ATHAPASCAN keyword `Fork` (We will see later how to use `Shared`). Assume we want to print to the console data about the task execution, for example: which processor is involved, which node number, etc... Here is a basic example

code :

```
#include "athapascan-1.h"

struct getInfoTask {
    void operator()(int i) {
        cout << "Task number: " << i << endl;
        cout << "Node number" << a1_system::self_node()
             << " out of " << a1_system::node_count() << endl;
        cout << "Thread number" << a1_system::self_thread()
             << " out of " << a1_system::thread_count() << endl;
    }
};

int doit(int argc, char** argv)
{
    for (int i=0; i<10; i++) {
        a1::Fork<getInfoTask>()(i);
    }
    return 0;
}

int main( int argc, char** argv )
{
    //MAIN METHOD AS PREVIOUSLY DEFINED IN API CHAPTER

    return 0;
}
```

This program is very simple and shows you how to write a task. Fork is instantiated with the class `getInfoTask` and will execute the code of the method overloading operator `()`.

### Compiling :

Recall that compiling an ATHAPASCAN program is done by executing the `make` function from the command line. For the `getInfoTask` example execute:

```
sh> make getInfoTask
```

To execute this newly created program enter the following on the command line:

```
sh> ./getInfoTask
```

NB: To run a program build upon LAM-MPI (like the ATHAPASCAN library) or Inuktitut, you have to configure your cluster of machines so that they can run a "rsh" to each other.

### 4.2.2 Simple Example 2: "Fibonacci.cpp" (multiple Fork and Shared)

#### algorithm :

The Fibonacci series is defined as:

$$\begin{cases} F(0) = 0 \\ F(1) = 1 \\ F(n) = F(n-1) + F(n-2) \quad \forall n \geq 2 \end{cases}$$

There are different algorithms to resolve Fibonacci numbers, some having a linear time complexity  $\Theta(n)$ . The algorithm we present here is a recursive method.

It is a very bad implementation as it has an exponential complexity,  $\Theta(2^n)$ , (as opposed to the linear time complexity of other algorithms). However, this approach is easy to understand and to parallelize.

#### Sequential implementation :

First, let's have a glance at the regular recursive sequential program:

```
#include <iostream.h>
#include <stdlib.h>

int fibonacci(int n) {
    if (n<2)
        return n;
    else
        return fibonacci(n-1)+fibonacci(n-2);
}

int main(int argc, char** argv)
{
    //make sure there is one parameter
    if (argc <= 1) {
        cout << "usage: fibonacci <N>" << endl;
        exit(1);
    }
    cout << "result= " << fibonacci(atoi(argv[1])) << endl;

    return 0;
}
```

#### Parallel implementation :

We assume that you wish to make this program parallel. An easy way to do it would be to use the same algorithm (recursive). Well, it's not that easy. Two reasons for that:

1. in the sequential program, we used a function while ATHAPASCAN only supports procedure (void function).
2. you can access shared data only from a task having this data as a parameter (ex: you can't display the value of a Shared from the main)

To write this parallel program, we will then need:

- a task doing the same job the sequential function was doing (recursive);
- a task to add the result of the two recursive calls to fibonacci;
- a task to print the result to stdout.

```

#include <athapascal-1>
#include <iostream>
#include <stdlib.h>

struct add {
    // This procedure sums two integers in shared memory and writes the
    // result in shared memory.
    void operator() ( a1::Shared_r<int> a, a1::Shared_r<int> b, a1::Shared_w<int> c ) {
        c.write( new int( a.read() + b.read() ) );
    }
};

struct fibonacci {
    // This procedure recursively computes fibonacci(n), where n is an int, and
    // writes the result in the shared memory.
    void operator() ( int n, a1::Shared_w<int> res ) {
        if( n < 2 )
            res.write( new int( n ) );
        else {
            a1::Shared<int> res1( 0 );
            a1::Shared<int> res2( 0 );

            a1::Fork< fibonacci > () ( n - 1 , res1 );
            a1::Fork< fibonacci > () ( n - 2 , res2 );

            a1::Fork< add > () ( res1, res2, res );
        }
    }
};

struct print {
    // This procedure writes to stdout, the result of fibo(n), where n is an int, in the
    // shared memory.
    void operator() ( int n, a1::Shared_r<int> res ) {
        cout << "Fibonacci(" << n << ") = " << res.read() << endl;
    }
};

int doit(int argc, char** argv)
{
    a1::Shared<int> res = int(0) ;

    a1::Fork<fibonacci> () (atoi(argv[1]), res );
    a1::Fork<print> () (atoi(argv[1]), res );
    return 0;
}

int main( int argc, char** argv )
{
    //MAIN METHOD AS PREVIOUSLY DEFINED IN API CHAPTER

    return 0;
}

```

**Explanation:** The purpose of this exercise is to share the Fibonacci computation with others processors. Therefore, we need to define a Shared data in order to hold the result and to create a task calling the Fibonacci function. The fibonacci task works the same way the sequential function works: first we check if  $n < 2$ ; if not we make recursive calls to get  $F(n - 1)$  and  $F(n - 2)$ .

The difference here is that we cannot directly access Shared data. Thus, we cannot add the two results directly, and therefore need temporary Shared variables and a specific task to add them.

### **An other parallel implementation using concurrent write :**

The parallel implementation we have just studied runs correctly but is not very efficient. This program will run faster if we use one of ATHAPASCAN's features called "concurrent write". This kind of Shared data is designed so that every task can access the data and perform a concurrent `cumul` operation. This means less synchronization needs to take place and thus, less time is wasted waiting for other tasks to complete. Ideally, the granularity of the tasks we wrote is not big since forking tasks can sometimes consume more CPU time than a regular sequentially executed task. The best way to increase the speed of the computation is then to Fork enough tasks for each processor to be busy, and then let them carry on sequentially to avoid excessive communication. For that purpose, we introduce a threshold variable. As indicated in the text, the threshold is user defined. Now examine the second parallel implementation of a Fibonacci number algorithm, Section ?? page ??.

NB: The parallel programs we present here are just for educational purpose. The granularity of the tasks executed on remote nodes is small while the number of tasks is high. If you try to run these programs on different architecture in order to compare the performances, you will realize that it can take even more time to execute in parallel than sequentially. This is a normal behavior for these kinds of programs.

```

#include "athapascal-1.h"
#include <iostream.h>
#include <stdlib.h>

struct add {
    //this method is instanciated by the cumul method of
    //the concurrent write Shared data (see fibonacci)
    void operator()(int & x, const int& a) { x += a ; }
};

//sequential fibonacci
int fibo_seq( int n ){
    if( n<2 )
        return n;
    else
        return( fibo_seq( n-1 ) + fibo_seq( n-2 ) );
}

struct fibonacci {
    void operator()( int n, int threshold, a1::Shared_cw< add, int > r ){
        if( n <= threshold ) {
            r.cumul( fibo_seq( n ) );
        } else {
            a1::Fork<fibonacci> () ((n-2),threshold , r );
            fibonacci() ((n-1), threshold, r );
        }
    }
};

struct print {
    // This procedure writes to stdout, the result of fibo(n),
    //where n is an int, in the shared memory.
    void operator() ( int n, a1::Shared_r<int> res ) {
        cout << "Fibonacci(" << n << ")= " << res.read() << endl;
    }
};

int doit(int argc, char** argv)
{
    a1::Shared<int> res = int(0) ;

    a1::Fork<fibonacci> () (atoi(argv[1]), atoi(argv[2]), res );
    a1::Fork<print> () (atoi(argv[1]), res );
    return 0;
}

int main( int argc, char** argv )
{
    //MAIN METHOD AS PREVIOUSLY DEFINED IN API CHAPTER

    return 0;
}

```

As you reach this point you should now be able to write, compile, and run a simple ATHAPASCAN based program. If you desire to write a real-life, more complex application you must further study the ATHAPASCAN library. There are many useful concepts that have not yet been introduced.

## 5 Tasks

The granularity of an algorithm is explicitly given by the programmer through the **creation of tasks** that will be **asynchronously** executed. A task is an object representing the association of a procedure and some effective parameters. Tasks are dynamically created at run time. A task (creation + execution) in ATHAPASCAN can be seen as a standard procedure call. The only difference is that the created task's execution is fully asynchronous, meaning the creator is not waiting for the execution of the created task to finish to continue with its own execution. An ATHAPASCAN program can be seen as a set of tasks scheduled by the system and distributed among nodes for its execution.

### 5.1 Task's Procedure Definition

A task corresponds to the execution of a C++ function object, *i.e.* an object from a class having the `void operator()` defined:

```
struct user_task {
    void operator() ( [...parameters...] ) {
        [... body ... ]
    }
};
```

A sequential (hence *not* asynchronous !) call to such a function class is written in C++:

```
user_task() ( [... effective parameters ...] ) ;
// user_task is executed according to depth-first ordering.
```

Pay attention to the type of the effective parameters when performing a sequential call of a struct. The type of the effective parameters must exactly match the type of the corresponding formal parameters! For example, a `Shared` parameter cannot be used where a `Shared_r` parameter is required. However when **Forking** a task, this behavior is allowed (see ?? page ?? to learn more about passing `Shared` parameters in ATHAPASCAN).

A task is an object of a user-defined type that is instantiated with `Fork` :

```
a1::Fork< user_task > () ( [... effective parameters ...] ) ;
// user_task is executed asynchronously.
// The synchronizations are defined by the access on
// the shared objects ; the semantic respects the
// reference order.
```

**Example** The task `hello_world` displays a message on the standard output:

```
struct hello_world {
    void operator() () { // No parameters here
        cout << "Hello world !" << endl ;
    }
};
int doit () {
    hello_world() () ; // immediate call (*not* asynchronous !)

    a1::Fork< hello_world > () (); // Creation of a task executed asynchronously.
    a1::Fork< hello_world > () (); // Creation of another task executed asynchronously.

    return 0;
}
int main( int argc, char**argv ) {
    // MAIN METHOD AS PREVIOUSLY DEFINED IN API CHAPTER

    return 0;
}
```

**Remark: encapsulating a C procedure.** Obviously, a C procedure (i.e. a C function with void as return type) can be directly encapsulated in a C++ function class and thus parallized with ATHAPASCAN. Here is an example:

```
void f ( int i ) {
    printf( "what could I compute with %d ? \n", i );
}
struct f_encapsulated {
    void operator() ( int i ) { /* i is some formal parameter */
        f( i );
    }
};
int doit() {
    int a = 3 ;
    ...
    f( a );                // Sequential call to the function f
    f_encapsulated() ( a ); // Sequential call to the function class
                           // f_encapsulated
    a1::Fork< f_encapsulated >() ( a ); // Asynchronous call to the function class
                           // f_encapsulated
    ...
    return 0;
}
int main( int argc, char**argv ){
    // MAIN METHOD AS PREVIOUSLY DEFINED IN API CHAPTER

    return 0;
}
```

## 5.2 Allowed Parameter Types

The system has to be able to perform the following with a task in order to “Fork” it:

1. detect its interactions with the shared memory in order to be able to determine any synchronizations required by the semantic.
2. move it to the node where its execution will take place.

Here are the different kinds of parameters allowed for a task

- `T`, to designate a classical C++ type that does not affect shared memory. However this type must be communicable (see Chapter ?? entitled Shared Memory for a definition of communicable types).
- `Shared_... < T >` to designate a parameter that is a reference to a shared object located in the shared memory. `T` is the type of this object. It must be communicable.

In the case of a classical `T` class, the type `T` should not refer to the shared memory. For example, when initializing a shared object `a1::Shared< T > s(d)`; where `d` points to an object of type `T`, this pointer should no longer be used in the program.<sup>1</sup>

## 5.3 Task Creation

To create an ATHAPASCAN task the keyword `a1::Fork` must be added to the usual procedure call. Here, `user_task` is a function class as described in the previous section:

C++ function object call	ATHAPASCAN task creation
...	...
<code>user_task() ( [args] );</code>	<code>a1::Fork&lt; user_task &gt;() ( [args] );</code>
...	...

The new created task is managed by the system which will execute it on a virtual processor of its choice (*cf.* Appendix ??).

## 5.4 Task Execution

The task execution is ensured by the ATHAPASCAN system. The following properties are respected:

- The task execution will respect the synchronization constraints due to the shared memory access;
- all the created tasks will be executed once and once only,
- no synchronization can occur in the task during its execution. Hence, for most but not all implementations of ATHAPASCAN programs the system guarantees that every shared data accessed for either reading or updating is available in the local memory before the execution of the task begins.

## 5.5 Kinds of Memory a Task Can Access

Each ATHAPASCAN task can access three levels of memory:

- the **stack**, a local memory private to the task. This local memory contains the parameters and local variables (it is the classical C or C++ stack).  
This stack is automatically deallocated at the end of the task.
- The **heap**, the local memory of the node (Unix process) that executes the task. Objects are allocated or deallocated in or from the heap directly using C/C++ primitives: `malloc`, `free`, `new`, `delete`...  
Therefore, all tasks executed on a given node share one common heap<sup>2</sup>: consequently, if a task does not properly deallocate the objects located in its heap, then some future tasks may run short of memory on this node.

<sup>1</sup>Caution: this is *not* verified, either at compile nor at execution time. The user has to take care of not including any reference on the shared memory in classical types.

<sup>2</sup>In the current implementation, the execution of a task on a node is supported by a set of threads that share the heap of a same heavy process representing the node.

- The **shared memory**, accessed concurrently by different tasks. The shared memory in ATHAPASCAN is a non-overlapping collection of physical objects (of communicables types) managed by the system.

## 6 Communicable Type

Using a distributed architecture means handling data located in shared memory (mapping, migration, consistency). In order to make ATHAPASCAN able to do this, the data must be serialized. This serialization has to be explicitly done by the programmer to suit the specific needs of the program.

NB: All the classes and types used as task parameters must be made communicable.

### 6.1 Predefined Communicable Types

The following types are communicable:

- The following C++ basic types: `short`, `unsigned short`, `int`, `unsigned int`, `long`, `unsigned long`, `char`, `unsigned char`, `float`, `double`, `long double`, `char*`<sup>3</sup>, `void*`.
- all types from the STL<sup>4</sup>.

Note that two generic functions for packing/unpacking an array of contiguous elements are provided:

```
a1::Ostream& a1_pack ( a1::Ostream& out, const T* x, int size ) ;
a1::Istream& a1_unpack ( a1::Istream& in,          T* x, int size ) ;
```

Both functions require the number of elements. They are specialized for basic C++ types.

### 6.2 Serialization Interface for Classes Stored in Shared Memory

A communicable type T must have the following functions:

- The empty constructor: `T()`
- The copy constructor: `T( const T& )`  
NB: the copy shall not have any overlap with the source.
- The destructor: `~T()`  
NB: only one task executes the deallocation at a time.
- The “sending” operator, `a1::Ostream& operator<<( a1::Ostream& out, const T& x )` puts into the output stream out the information needed to reconstruct an image of x using the operator `>>`.
- The “receiving” operator, `a1::Istream& operator>>( a1::Istream& in, T& x )` takes from the input stream in the information needed to construct the object x; it allocates and initializes x with the value related to the information.  
Note that the system always calls this function with an object x that has been constructed with the empty constructor.

### 6.3 Examples

This section teaches through examples how to define a class or type as being communicable. The three examples provided in this section are Complex Numbers (which creates a simple communicable class), Basic List with Pointers (which generates a singly-linked list which behaves as a queue data structure), and Resizable Array (which generates a class for the creation of a list of dynamic size).

#### 6.3.1 Example 1: Complex Numbers

For example, let us consider the complex numbers type. This type can be set “communicable” by simply implementing the four communication operators.

NB: Note that the C++ provided defaults can often be used to impliment the empty constructor, the copy constructor and the destructor. In the case of the `complex` type, the defaults operators are used (refer to a C++ guide to learn more about these defaults constructors).

<sup>3</sup>You must be careful when communicating pointers : in fact if your program is executed on several nodes (option `-a0n 2` for example), the communication can be performed between the nodes and the pointer is often meaningless on other nodes.

<sup>4</sup>By default the system considers that all types possess iterators that run all over the data: this is the case of STL types. For all others, the necessary functions have to be provided to override this default definition.

```

/**
    class complex is an Athapascan-1 communicable class
    complex:  $z = x + i*y$ 
    NB: This class implements only the methods needed
    by Athapascan-1.
 */
class complex {
public:
    double x;
    double y;

    //empty constructor
    complex() { x=0; y=0;}

    //copy constructor
    complex( const complex& z) { x=z.x; y=z.y;}

    //destructor
    ~complex() {}

};

//packing operator
a1::Ostream& operator<< (a1::Ostream& out, const complex& z) {
    out << z.x << z.y;
    return out;
}

//unpacking operator
a1::Istream& operator>> (a1::Istream& in, complex& z) {
    in >> z.x >> z.y;
    return in;
}

```

Figure 1: Making the user defined class, complex, communicable

### 6.3.2 Example 2: Basic List with Pointers

Let's go a bit deeper in the serialization and find out how to write a communicable class implementing a dynamic data structure based upon a list of pointers.

NB: Even though the container classes from the STL are optimized and have been made communicable, there is little use for these classes in a real-life ATHAPASCAN application. Therefore the class in this example is not optimized, it is just an example. This class implements a chain structure using pointers. When running parallel application on a cluster of machines, it is meaningless to communicate addresses. Therefore, we just communicate values:

The following class implements a chain structure using pointers. When running a parallel application on a cluster of machines, it is meaningless to communicate addresses. Therefore, only values are communicated:

- *a1::Ostream*: we send first the number of values, then the values themselves (but we don't send the pointers!);
- *a1::Istream*: we receive first the number of values, then we insert the values in the chain (using local pointers).

---

```

#include <iostream.h>
#include <stdlib.h>
#include "athapascal-1.h"

/**
   class myList is an Athapascal-1 communicable class
   We use a chain structure to store the values.
   NB: T has to be communicable too.
 */

template<class T>
class myList {
public:
    T value;
    myList* next;

    //empty constructor
    myList() : value(), next(0) {}

    //constructor
    myList(T v, myList* n): value(v), next(n) {}

    //copy constructor
    myList(const myList<T>& d) {
        value = d.value;
        if (d.next != 0) {
            next = new myList<T> (*(d.next));
        } else next = 0;
    }

    //destructor
    ~myList() {
        if (next != 0) delete next;
    }

    //return the size of the list
    int size() {
        int s(0);
        myList<T>* x = this;
        while(x->next != 0) {
            s++;
            x = x->next;
        }
        delete x;
        return s;
    }

    //we push the data at the end of the list
    void push_back(T newval) {
        myList<T>* x = this;
        while(x->next != 0) x = x->next;
        x->next = new myList(newval, 0);
    }

    //we pop the first data from the list, remove it and return its value
    T pop_front() {
        if (!next) return -1;
        else {
            myList<T>* x = next;
            T ret = next->value;
            next = x->next;
            x->next = 0;
            delete x;
            return ret;
        }
    }
};

//packing operator
template<class T>

```

10

20

30

40

50

60

70

---

```

a1::Ostream& operator << (a1::Ostream& out, const myList<T>& z) {
    myList<T> x = z;
    out << x.size();
    while(z.next != 0) {
        out << z.value;
        x = *(x.next);
    }
    out << x.value;
    return out;
}
80

//unpacking operator
template<class T>
a1::Istream& operator >> (a1::Istream& in, myList<T>& z) {
    int size;
    int temp(0);

    in >> size;
    for(int i(0); i<size; i++) {
        in >> temp;
        z.push_back(temp);
    }
    return in;
}
90

//test tasks to see if the class is communicable
struct myTaskW {
    void operator()(a1::Shared_r_w<myList<int> > x) {
        for(int i(0); i<100 ; i++) {
            x.access().push_back(i);
        }
    }
};
100

struct myTaskR {
    void operator()(a1::Shared_r_w<myList<int> > x) {
        myList<int> z = x.access();
        while (z.next!=0) {
            cout << z.pop_front() << " ";
        }
    }
};
110

int doit( int argc, char** argv )
{
    a1::Shared<myList<int> > x(new myList<int>());
    a1::Fork<myTaskW> () (x);
    a1::Fork<myTaskR> () (x);
    return 0;
}
120

```

---

### 6.3.3 Example 3: Resizable Array

A simple example of a dynamic structure is a mono-dimensional array with two fields: a size 'size' and a pointer to an array with 'size' number of elements.

---

```

#include <iostream.h>
#include <stdlib.h>
#include <string.h>
#include "athapascal-1.h"

/**
   class myArray is an Athapascal-1 communicable class
   implementing a resizable myArray.
   NB: T has to be communicable too.
 */
10

template<class T >
class myArray {
public:
    unsigned int size; // The size of the myArray.
    T* elts;           // ith entry is accessed by elts[i].

    //empty constructor
    myArray() : size(0), elts( 0 ) {}

    //constructor
    myArray(unsigned int k) : size(k) {
        if (size==0) elts=0;
        else elts = new T [size];
    }

    //copy constructor
    myArray(const myArray<T>& a) {
        size = a.size;
        elts = new T [size];
        for (int i=0; i<size; i++) elts[i] = a.elts[i] ;
    }

    //destructor
    ~myArray() { delete [] elts ; }

    //resize the myArray
    void resize(unsigned int newSize);

};
40

// Packing operator
template<class T >
al_ostream& operator<< ( al_ostream& out, const myArray<T>& z ) {
    out << z.size ;
    for (int i = z.size-1; i>=0 ; i--) out << z.elts[i] ;
    return out;
}

// Unpacking operator
template<class T >
50
al_istream& operator>> ( al_istream& in, myArray<T>& z ) {
    in >> z.size ;
    z.elts = new T [ z.size ] ;
    for (int i = z.size-1; i>=0 ; i--) in >> z.elts[i] ;
    return in;
}

void myArray<T>::resize(unsigned int newSize) {
    //erasing the data
    if (newSize <= 0) {
        size = 0;
        if (elts != NULL) {delete elts; elts=0;}
        return;
    }

    //new myArray is smaller
60

```

---

```

    if (newSize <= size) {
        T* newtab = new T[newSize];
        memmove(newtab, elts, newSize*sizeof(T));
        delete elts;
        elts = newtab;
        size = newSize;
        return ;
    }

    //then new myArray is bigger
    T* newtab = new T[newSize];
    memmove(newtab, elts, size * sizeof(T));
    delete elts;
    elts = newtab;
    size = newSize;
    return ;
}

//test tasks to see if the class is communicable
struct myTaskW {
    void operator()(a1::Shared_r_w<myArray<int> > x) {
        int z = x.access().size;
        for(unsigned int i(0); i < z ; i++) {
            x.access().elts[i] = 2*i;
        }
    }
};

struct myTaskR {
    void operator()(a1::Shared_r_w<myArray<int> > x) {
        cout << "size of the array: " << x.access().size << endl;
    }
};

struct resizeTab {
    void operator()(a1::Shared_r_w<myArray<int> > x, unsigned int n) {
        x.access().resize(n);
    }
};

int doit( int argc, char** argv )
{
    a1::Shared<myArray<int> > x(new myArray<int>(100));
    a1::Fork<myTaskW> () (x);
    a1::Fork<myTaskR> () (x);
    a1::Fork<resizeTab> () (x, 10);
    a1::Fork<myTaskR> () (x);

    return 0;
}

int main( int argc, char** argv )
{
    //MAIN METHOD AS PREVIOUSLY DEFINED IN API CHAPTER

    return 0;
}

```

---

## 7 Shared Memory: *Access Rights* and *Access Modes*

Shared memory is accessed through typed references. One possible type is `Shared`. The consistency associated with the shared memory access is that each “read” sees the last “write” according to the lexicographic order.

Tasks **do not make any side effects** on the shared memory of type `Shared`. Therefore they can only access the shared data on which possess a reference. This reference comes either from the declaration of some shared data or from some effective parameter. A reference to some shared data is an object with the following type: `a1::Shared_RM < T >`. The type `T` of the shared data must be communicable (see Section ?? page ??). The suffix `RM` indicates the access right on the shared object (read – `r` –, write – `w` – or cumul – `c` –) and the access mode (local or postponed – `p` –) `RM` can be one of the following suffixes:

`r`, `rp`, `w`, `wp`, `cw`, `cwp`, `r_w` and `rp_wp`.

Access rights and modes are respectively described in section ?? page ?? and ?? page ??.

### 7.1 Declaration of Shared Objects

If `T` is a communicable type, the declaration of an object of type `a1::Shared<T>` creates a new shared datum (in the shared memory managed by the system) and returns a reference to it.

Depending on whether the shared object is initialized or not, three kinds of declarations are allowed:

- `a1::Shared< T > x( new T( ... ) );`

The reference `x` is initialized with the value pointed to by the constructor parameter. Note that the memory being pointed to will be deallocated by the system and should not be accessed anymore by the program. `x` can not be accessed by the task that creates it. It is only possible to Fork other tasks with `x` as an effective parameter.

Example:

```
a1::Shared<int> x ( new int( 3 ) ) ;
    // x is initialized with the value 3.

double* v = new double ( 3.14 ) ;
a1::Shared<double> sv ( v ) ;
    // sv is initialized with the value v;
    // v can not be used anymore in the program
    // and will be deleted by the system.
```

- `a1::Shared< T > x( 0 );`

The reference `x` is declared but not initialized. Thus, the first task that will be forked with `x` as parameter will have to initialize it, using a write statement (?? page ??). Otherwise if a task receives this reference as a parameter and attempts to read a value from it, dead-lock will occur.

Example:

```
a1::Shared<int> a (new int(0) ) ;
    // a is a shared object initialized with the value 0.
a1::Shared<int> x ( 0 ) ;
    // x is a NON initialized shared object.
```

- `a1::Shared< T > x;`

The reference `x` is only declared as a reference, with no related value. `x` therefore has to be assigned to another shared object before forking a task with `x` as a parameter. Such an assignment is symbolic, having the same semantics as pointer assignment.

Example:

```

a1::Shared<int> x ;
    // x is just a reference, not initialized.
a1::Shared<int> a (new int(0) );
    // a is a shared object initialized with the value 0.
x = a ;
    // x points to the same shared object as a.

```

The following operations are allowed on an object of type **Shared**:

- Declaration in the stack, as presented above.
- Declaration in the heap, using the operator `new` to create a new shared object. In the current implementation, the “link” between a task and a shared data version is made through the C++ constructor and destructor of the shared object. So, to each construction must correspond a destruction, else dead-lock may occur. Therefore, in the case of allocation in the heap, the `delete` operator corresponding to the already executed `new` has to be performed.
- Affectation: a shared object can be affected from one to another. This affectation is symbolic, having the same semantics as pointer affectation. The “real” shared object is then accessed through two distinct references.

## 7.2 Shared Access Rights

In order to respect the sequential consistency (lexicographic order semantic), ATHAPASCAN has to identify the value related to a shared object for each read performed. Parallelism detection is easily possible in the context that any task specifies the shared data objects that it will access during its execution (on-the-fly detection of independent tasks), and which type of access it will perform on them (on-the-fly detection of a task’s precedence). Therefore, an ATHAPASCAN task can not perform side effects. All manipulated shared data must be declared in the prototype of the task. Moreover, to detect the synchronizations between tasks, according to lexicographic semantic, any shared parameter of a task is tagged in the prototype of `t` according to the access performed by `t` on it. This tag indicates what kind of manipulation the task (and, due to the lexicographic order semantics, all the sub-tasks it will fork) is allowed to perform on the shared object. This tag is called the access right; it appears in the prototype of the task as a suffix of the type of any shared parameter. Four rights can be distinguished and are presented below: read, write, update and accumulation.

### 7.2.1 Read Right: `Shared_r`

`a1::Shared_r< T >` is the type of a parameter whose value can only be read. This reading can be concurrent with other tasks referencing this shared object in the same mode.

In the prototype of a task, the related type is:

```
a1::Shared_r< T > x
```

Such an object gets the method:

```
const T& read () const ;
```

that returns a constant reference to the value related to the shared object `x`.

For example, using the Class `complex` that is defined in `??`:

```

class print {
    void operator() ( a1::Shared_r< complex > z ) {
        cout << z.read().x << " + i." << (z.read()).y ;
    }
};

```

### 7.2.2 Write Right: `Shared_w`

`a1::Shared_w< T >` is the type of a parameter whose value can only be written. This writing can be concurrent with other tasks referencing this shared data in the same mode. The final value is the last one according to the reference order. In the prototype of a task, the related type is:

```
a1::Shared_w< T > x
```

Such an object gets the method:

```
void write ( T* address ) ;
```

that assigns the value pointed to by `address` to the shared object.

This method assigns the value pointed to by `address` to the shared object. No copy is made: the data pointed by `<address>` must be considered as lost by the programmer. Further access via this address are no more valid (in particular, the deallocation of the pointer: it will be performed by the system itself).

Example:

```
class read_complex {
    void operator() ( a1::Shared_w< complex > z ) {
        complex* a = new complex ;
        cin >> a.x >> a.y ;
        z.write ( a ) ;
    }
};
```

**Note** To clarify the rule that each `read` "sees" the last `write` due to lexicographical order being observed, follow the example below:

```
#include "athapascal-1.h"
#include <stdio.h>

struct my_read {
    void operator()( a1::Shared_r<int> x ) {
        printf( " x=%i\n", x.read() );
    }
};

struct my_write {
    void operator()( a1::Shared_w<int> x, int val ) {
        x.write( new int(val) );
    }
};

int doit( int argc, char** argv )
{
    a1_system::init(argc, argv);
    a1_system::init_commit();
    if( a1_system::self_node() == 0 ) {
        a1::Shared<int> i( new int( 1 ) );
        a1::Fork<my_write>()( i, 1 ); // line A
        a1::Fork<my_read>()( i ); // line B
        a1::Fork<my_write>()( i, 2 ); // line C
        a1::Fork<my_read>()( i ); // line D
        a1::Fork<my_write>()( i, 3 ); // line E
        a1::Fork<my_read>()( i ); // line F
    }
    a1_system::terminate();

    return 0;
}

int main( int argc, char** argv )
{
    //MAIN METHOD AS PREVIOUSLY DEFINED IN API CHAPTER

    return 0;
}
```

It is possible that the operations in line E and then in line F will execute before the preceeding lines because the rule described above is not broken. So do not be surprised to see the following result on the screen:

```
x=3
x=2
x=1
```

Keep this in mind, especially when measuring the time of computations. In that case of adding some extra synchronization variables to the code. But be careful because this can decrease the efficiency with which the program runs.

### 7.2.3 Update Right: Shared\_r\_w

`a1::Shared_r_w< T >` is the type of a parameter that's value can be updated in place; the related value can be read and/or written. Such an object represents a critical section for the task. This mode is the only one where the address of the physical object related to the shared object is available. It enables the user to call sequential codes working directly with this pointer.

In the prototype of a task, the related type is:

`a1::Shared_r_w< T > x`

Such an object gets the method:

`T& access ( ) ;`

that returns a reference on the data contained by the shared referenced by `x`. Note that `&(x.access())` is constant during all the execution of the task and can not be changed by the user.

Example:

```
class incr_1 {
    void operator() ( a1::Shared_r_w< int > n ) {
        n.access() = n.access() + 1 ;
    }
}
```

### 7.2.4 Accumulation Right: Shared\_cw

`a1::Shared_c< T >` is the type of a parameter whose value can only be accumulated with respect to the user defined function class `F`. `F` is required to have the prototype:

```
struct cumul_fn {
    void operator() ( T& x, const T& y ) {
        ... // body to perform x <-- accu(x, y)
    }
} ;
```

Example:

```
struct add {
    void operator ( ) (int& x, int& y) {
        x+=y;
    }
};
```

The resulting value of the concurrent write is an accumulation of all other values written by a call to this function. After the first accumulation operation is executed, the initial value of `x` becomes either the previous value or remains the current value, depending on the lexicographic access order. If the shared object has not been initialized, then no initial value is considered. Since an accumulation enables a concurrent update of some shared object, the accumulation function `F` is assumed to be both *associative* and *commutative*. Note that only the accumulations performed with respect to a same law `F` can be concurrent. If different accumulation functions are used on a single shared datum, the sequence of resulting values obeys the lexicographic order semantics.

In the prototype of a task, the related type is:

`a1::Shared_cw< F, T > x`

Such an object gets the method:

`void cumul (T& v ) ;` that accumulates (according to the accumulation function `F`) `v` in the shared data referenced by `x`. For the first accumulation a copy of `v` may be taken if the shared data version does not contain some valid data yet.

Example:

```
// A generic function class that performs
// the multiplication of two values.
template < class T >
class multiply {
    void operator( T& x, const T& val ) {
        x = x * y ;
    }
};

// A task that multiplies by 2 a shared object
class mult_by_2 { //
    void operator() ( a1::Shared_cw< multiply<int>, int > x) {
        x.cumul ( new int(2) ) ;
    }
};
```

**Note**

Keep in mind that a program written in ATHAPASCAN can benefit at run-time from the associative and commutative properties of the accumulation function F. It is therefore possible that the execution of the code in Figure ?? will result in:

```
x=3 val=2
x=5 val=1
```

```
#include "athapascan-1.h"
#include <stdio.h>

struct F {
    void operator()( int & x, const int & val ) {
        printf( " x=%i val=%i\n", x, val );
        x += val;
    }
};

struct add {
    void operator()( a1::Shared_cw<F,int> x, int val ) {
        x.cumul( val );
    }
};

int doit( int argc, char** argv )
{
    a1::Shared<int> i( new int( 1 ) );
    a1::Fork<add>()( i, 2 );
    a1::Fork<add>()( i, 3 );
    return 0;
}

int main( int argc, char** argv )
{
    //MAIN METHOD AS PREVIOUSLY DEFINED IN THE API CHAPTER

    return 0;
}
```

Figure 2: Demonstration of associativity and commutativity of cumulative mode

It may seem as though the program was implemented according to the sequential depth-first algorithm:

```
.....
a1::Shared<int> i( new int( 3 ) );
```

```
a1::Fork<add>()( i, 2 );  
a1::Fork<add>()( i, 1 );  
.....
```

This is not the case. Naturally the above code is semantically correct as well and could produce the same result as the program in ???. It is therefore important to realize that since the function  $F$  is associative and commutative, the precise manner in which the reductions are performed cannot be predicted, even in the case where initial values are known.

### 7.3 Shared Access Modes

In order to improve the parallelism of a program when only a reference to a value is required - and not the value itself - ATHAPASCAN refines its access rights to include *access modes*. An access mode categorizes data by restricting certain types of access to the data. By default the access mode of a shared data object is “immediate”, meaning that the task may access the object using any of the `write`, `read`, `access` or `cumul` methods during its execution. An access is said to be “postponed” (access right suffixed by `p`) if the procedure will not directly perform an access on the shared data, but will instead create other tasks that may access the shared data. In functional languages, such a parallelism appears when handling a reference to a future value.

With this refinement to the access rights, ATHAPASCAN is able to decide with greater precision whether or not two procedures have a precedence relation. A procedure requiring a shared parameter with a direct read access, `r`, has a precedence relation with the last procedure to take this same shared parameter with a write access. However, a procedure taking some shared parameter with a postponed read access, `rp`, has no precedence relation. It is guaranteed by the access mode that no access to the data will be made during the execution of this task. The precedence will be delayed to a sub-task created with a type `r`. In essence, the type `Shared` can be seen as a synonym for the type `a1::Shared_rp_wp<T>`; it denotes a shared datum with a read-write access right, but on which no access can be locally performed. An object of such a data type can thus only be passed as an argument to another procedure.

#### 7.3.1 Conversion Rules

When forking a task `t` with a shared object `x` as an effective parameter, the access right required by the task `t` has to be owned by the caller. More precisely, the Figure ?? page ?? enumerates the compatibility, at task creation, between a reference on a shared object type and the formal type required by the task procedure declaration. Note that this is available only for task creation, and not for standard function calls where the C++ standard rules have to be applied.

type of <i>formal parameter</i>	required type for the <i>effective parameter</i>
<code>a1::Shared_r[p] &lt; T &gt;</code>	<code>a1::Shared_r[p] &lt; T &gt;</code> <code>a1::Shared_rp_wp &lt; T &gt;</code> <code>a1::Shared&lt; T &gt;</code>
<code>a1::Shared_w[p] &lt; T &gt;</code>	<code>a1::Shared_w[p] &lt; T &gt;</code> <code>a1::Shared_rp_wp &lt; T &gt;</code> <code>a1::Shared&lt; T &gt;</code>
<code>a1::Shared_cw[p] &lt; F, T &gt;</code>	<code>a1::Shared_cw[p] &lt; F, T &gt;</code> <code>a1::Shared_rp_wp &lt; T &gt;</code> <code>a1::Shared&lt; T &gt;</code>
<code>a1::Shared_rp_wp &lt; T &gt;</code>	<code>a1::Shared_rp_wp &lt; T &gt;</code> <code>a1::Shared&lt; T &gt;</code>
<code>a1::Shared_r_w &lt; T &gt;</code>	<code>a1::Shared_rp_wp &lt; T &gt;</code> <code>a1::Shared&lt; T &gt;</code>

Figure 3: Compatibility rules to pass a reference on some shared data as a parameter to a task.

#### 7.3.2 Shared Type Summary

Figure ?? page ?? summarizes the basic properties of references on shared data.

Reference type	decl.	formal P	effectif P	read	write	cumul	modif	concurrent
<b>a1::Shared_r</b> < T >		•	•	•				•
<b>a1::Shared_rp</b> < T >		•	•	○				•
<b>a1::Shared_w</b> < T >		•	•		•			
<b>a1::Shared_wp</b> < T >		•	•		○			
<b>a1::Shared_cw</b> < F,T >		•	•			•		•
<b>a1::Shared_cwp</b> < F,T >		•	•			○		•
<b>a1::Shared_r_w</b> < T >		•		•	•		•	
<b>a1::Shared_rp_wp</b> < T >		•	•	○	○		○	
<b>a1::Shared</b> < T >	•		•	○	○		○	

Figure 4: Figure 6.3: Available types (and possible usages) for references on shared data. A • stands for a direct property and a ○ for a postponed one. *formal P* denotes formal parameters (type given at task declaration) and *effective P* denotes effective ones (type of object given at the task creation). *concurrent* means that more than one task may refer to the same shared data version.

## 7.4 Example: A Class Embedding ATHAPASCAN Code

A good way to write ATHAPASCAN applications is to hide ATHAPASCAN code in the data structures. Proceeding that way will allow you to keep your main program free from parallel instructions (making it easier to write and understand). In Chapter 5.3.3 we wrote a communicable class implementing a resizable, communicable array called `myArray`. We are now going to write a shared data structure on top of this class.

---

```
#include "athapascal-1.h"
#include "resizeArray.h"
```

```
/**
 * class shared_array is a class hiding Athapascal code so that
 * the main code of the application could be written as if it was
 * sequential. It is based upon the resizable array class called
 * myArray
 */
```

```
//resize the shared array
template<class T>
struct resize_shared_array {
    void operator() (a1::Shared_r_w<myArray<T > > tab, unsigned int size) {
        tab.access().resize(size);
    }
};
```

```
//affect a local myArray to a shared_array
template<class T>
struct equal_shared_array {
    //NB: we use a read/write access because we need the size
    void operator() (a1::Shared_r_w<myArray<T > > shtab, myArray<T> tab) {
        myArray<T>* t = new myArray<T>(tab);
        t->resize(shtab.access().size);
        shtab.access() = *t;
    }
};
```

```
//append a shared array to a shared array
template<class T>
struct append_shared_array {
    void operator() (a1::Shared_r_w<myArray<T > > t1, a1::Shared_r<myArray<T > > t2) {
        int i = t1.access().size;
        int k = i + t2.read().size;

        t1.access().resize( k );
        for (int j(i); j<k; j++) {
            t1.access().elts[j] = t2.read().elts[j-i];
        }
    }
};
```

10

20

30

40

```

};

//swap two elements of a shared array
template<class T>
struct swap_shared_array {
    void operator() (a1::Shared_r_w<myArray<T> > > tab, int i1, int i2) {
        T temp;

        temp = tab.access().elts[i1];
        tab.access().elts[i1] = tab.access().elts[i2];
        tab.access().elts[i2] = temp;
    }
};

//print the data of a shared array to standard output
template<class T>
struct ostream_shared_array {
    void operator() (a1::Shared_r<myArray<T> > > tab) {
        unsigned int size = tab.read().size;
        for (int i(0); i<size; i++) cout << tab.read().elts[i] << " ";
    }
};

template<class T>
class shared_array : public a1::Shared<myArray<T> > > {
public:
    //constructors
    shared_array() : a1::Shared<myArray<T> > >(new myArray<T>()) {}
    shared_array(unsigned int size) : a1::Shared<myArray<T> > >(new myArray<T>(size)) {}

    void resize(unsigned int newSize) {
        a1::Fork<resize_shared_array<T> > >() ((a1::Shared<myArray<T> > >&) *this, newSize);
    }

    void operator= (const myArray<T> &a) {
        a1::Fork<equal_shared_array<T> > >() ((a1::Shared<myArray<T> > >&) *this, a );
    }

    void append(shared_array &t2) {
        a1::Fork<append_shared_array<T> > >() ((a1::Shared<myArray<T> > >&) *this, (a1::Shared<myArray<T> > >&) t2);
    }

    void swap(int i1, int i2) {
        a1::Fork<swap_shared_array<T> > >() ((a1::Shared<myArray<T> > >&) *this, i1, i2);
    }
};

// ostream operator
template<class T>
ostream& operator<< ( ostream& out, const shared_array<T>& z ) {
    a1::Fork<ostream_shared_array<T> > >() ((a1::Shared<myArray<T> > >) z);
    return out;
}

```

---

The following main file tests the shared class. As you can see, there is no more reference to specific parallel code.

---

```

#include "athapascan-1.h"
#include "sharedArray.h"

#define SIZE 100

int doit( int argc, char** argv )
{
    shared_array<int> t1(10), t2(20);
    myArray<int> tab(SIZE);

    //fill the array
    for (int i(0); i< SIZE; i++) {

```

```
        tab.elts[i] = i;
    }

    //resize the shared array to test the methods
    t1.resize(SIZE);

    //move the data to the shared array
    t1 = tab;

    //try to swap a data
    t1.swap(2, 27);

    //append another shared array
    t2 = tab;

    t1.append(t2);
    cout << t1 << endl;
}

return 0;
}

int main( int argc, char** argv )
{
    //MAIN METHOD AS PREVIOUSLY DEFINED

    return 0;
}
```

---

## 8 Other Global Memory Paradigm

Access to shared data involve task synchronization: tasks are unable to perform side effects.

In some applications like Branch&Bound, it's convenient to share a variable with all other tasks, data that can be read and written by anybody. This variable usually contains the value of a reached minimum or maximum. No information with respect to another task's activity is associated with this variable.

We are currently in the process of finishing the implementation of global variables for Athapascan-1 (variables that can be both read and written on the collection of nodes in a community without the constraints of data dependency that exist for Shareds). Please bare with us as this project is still in development.

### 8.1 Memory Consistencies

The system offers three different consistencies on this memory:

- A Causal-Consistency where the data consistency is maintained along the paths of the precedence graph. That is to say that if the task  $T_1$  preceeds the task  $T_2$  in the precedence graph, then the modification on the memory made by  $T_1$  will be seen by  $T_2$ .
- A Processor Consistency where the data consistency is maintained among the virtual processors of the system. That is to say that the order of modification of the memory on a virtual processor  $P_1$  is the same that the order of modification seen on an other virtual processor  $P_2$ .
- An Asynchronous Consistency, where the data consistency is maintained on the system in its globality. That is to say that each modification made on one virtual processor will eventually be seen on other virtual processors.

### 8.2 Declaration

The declaration of a global data has the following prototype:

- `a1_mem_cc< T > x( T* pval );`  
for causal consistency
- `a1_mem_pc< T > x( T* pval );`  
for processor consistency
- `a1_mem_ac< T > x( T* pval );`  
for asynchronous consistency

The type `T` must be communicable and `pval` assigns a pointer to the initial value assumed by the object. This pointer can be null and is entirely managed by the system. That is to say, the pointer must be considered as lost by the programmer. This declaration is permitted anywhere in the code. An object of type `a1_mem` can be used as a parameter of a task or declared globally. If recieved as a parameter, the scope of the variable is limited to the procedure's body whereas it has the scope of the entire code if it is declared globally.

### 8.3 Registration

Due to some implementation characteristics, the global data have to be registered, effectively linking all the representatives (one per processor) to the same global data. If the object is used in the task parameters, this registration is made automatically. Otherwise if the object is declared globally the registration must be manually performed. Manually registering global data is done by invoking the `register( pval )` method on each object during the initialization phase, between the `a1_system::init()` and `a1_system::init_commit()` invocation. The `pval` parameter assigns a pointer to the initial value taken by the object. This pointer can be null and is entirely managed by the system, that is to say must be considered as lost by the programmer. The order of invocation must be the same <sup>5</sup> on all virtual processors.

<sup>5</sup>The result of registration is to associate an unique identifier to the object. This identifier result of an incrementation of a variable locale to the virtual processor. So two object are considered as identicall if their identifier are equal, that is to say if they have been registered at the same rank.

## 8.4 Usage

Three operations are allowed on an `a1_mem` object `x` representing a data of type `T`:

- The call `x.read()` returns a constant reference on the data located in `x`
- The call `x.write( pval )` writes the value pointed to by `x`. The pointer `T* val` must be considered as lost by the programmer.
- The call `x.fetch_and_op( int (*f)( T& a, const T& b ), val)`, where the object `val` is of type `const T&` and `f` designates a pointer to the funtion to be performed. The first parameter of this function will be the data stored in `x` and the second will be stored in `val`. The result of this function should be 1 if the data have been modified, otherwise it should be 0.

## 8.5 Destruction

The destruction of `a1_mem` objects is managed by the system and occurs:

- When no task possess it, for objects used as parameter
- At the end of the program execution, for objects that have been registered.

## 8.6 Example

The following example, Figure ?? shows the basic usage of `a1_mem` objects. The `complex` type is communicable and has been previously defined in Chapter ?? page ??.

```

a1_mem_cc< int > x( 0 );
a1_mem_pc< complex > z( 0 );

int min( int& a, const int& b ) {
    if( a<b )
        return 0;
    a= b;
    return 1;
}

task T1( a1_mem_ac< double > f ) {
    f.fetch_and_op( &min, 0.01 );
}

task T2( ) {
    if( x.read() > 5 )
        z.write( new complex( 1.2, 2.5 ) );
}

int a1_main( int argc, char* argv[] )
{
    a1_system::init();
    x.register( new int( 1 ) );
    y.register( new complex );
    a1_system::init_commit();

    ...

    a1_system::terminate();
    return 0;
}

```

Figure 5: Basic usage of `a1_mem` objects.

## 8.7 Consideration on Global Data

Global data permits side effects to occur, therefore, the guarantee of a sequential execution is not maintained if these data are used.

## 9 Examples

In this chapter, we present several complete examples of ATHAPASCAN programs. These examples are simple enough to be extensively presented within the confines of this chapter and complex enough to demonstrate the implementation of ATHAPASCAN in the context of real-world applications.

All these examples come with the library distribution.

### 9.1 Simple Parallel Quicksort

The aim of this implementation is to sort an array of data on two processors using an algorithm based upon a pivot. This implementation uses the class `myArray` (a resizable array as defined in ?? page ??) as well as the `shared_array` class (as defined in ?? page ??).

What we wish to show here is how to embed parallel instructions in the classes representing a user's data structures. Programming this way makes the main application code a lot more simple to understand and to write.

The idea of the algorithm is:

1. to split the array in two parts;
2. to sort each array in parallel (using `qsort`);
3. to split those arrays in two parts: elements  $<$  pivot and elements  $>$  pivot;
4. to merge the arrays containing data  $<$  pivot (and data  $>$  pivot);
5. to append the second array to the first one;

```
#include "sharedArray.h"
```

```
//qsort the array
```

```
template<class T>
```

```
struct qsort_my_shared_array {
```

```
    void operator() (a1::Shared_r_w<myArray<T > > t) {
        t.access().qsort();
    }
```

```
};
```

```
//find a pivot
```

```
template<class T>
```

```
struct fPiv_my_shared_array {
```

```
    void operator() (a1::Shared_r<myArray<T > > t, a1::Shared_w<T> pivot) {
        int middle = t.read().size / 2;
        T *result = new T((t.read().elts[middle] + t.read().elts[middle+1])/2);
        pivot.write(result);
    }
```

```
};
```

```
//copy part of a myArray to a my_shared_array
```

```
template<class T>
```

```
struct copy_my_shared_array {
```

```
    void operator() (a1::Shared_w<myArray<T > > t,
                    myArray<T> from,
                    int start,
                    int size)
```

```
    {
        int sizeMyArray = from.size;
        //error control
        //(is size of shared big enough to receive data from array?)
        if (size > sizeMyArray) {
            cerr << "ERROR copy: size of shared_array < size of myArray" ;
            cerr << endl;
            exit(1);
        }
        myArray<T> *temp = new myArray<T>(size);
        for (int i(0); i< size ; i++) temp->elts[i] = from.elts[i+start];

        t.write(temp);
    }
```

```
};
```

```
//copy part of a my_shared_array to a my_shared_array
```

```

## 9.2 Adaptative Quadrature: Integration by Newton-Cotes

The aim of this very simple divide and conquer strategy is to compute the integration of the function  $f$  on the interval  $[a, b]$  according to the Newton-Cotes method:

$$\int_a^b f dx = \int_a^{\frac{(a+b)}{2}} f dx + \int_{\frac{(a+b)}{2}}^b f dx$$

$$\forall |b - a| < h, g(a, b) = \int_a^b f dx$$

## NC.C

```

#include <athapascan-1.h>

double g(double a, double b)
{
    return (a*a+b*b)*(b-a)/2.0;
}

struct sum {
    void operator()(Shared_r<double> a, Shared_r<double> b, Shared_w<double> c){
        c.write(new double(a.read() + b.read()));
    }
};

struct compute {
    void operator()(double a, double b, Shared_r<double> h, Shared_w<double> res){
        if(b-a < h.read()) {
            res.write(new double(g(a,b)));
        } else {
            Shared<double> res1(new double);
            Shared<double> res2(new double);
            res1.graph_name("res1"); res2.graph_name("res2");

            Fork<compute>() (a, (a+b)/2, h, res1);
            Fork<compute>() ((a+b)/2, b, h, res2);

            Fork<sum>() (res1, res2, res);
        }
    }
};

### 9.3 Scalar Product

This example shows the use of a cumulative shared and of an array of parameters. Parameter arrays are recursively split until their sizes are 1. Then the result is accumulated in a shared data.

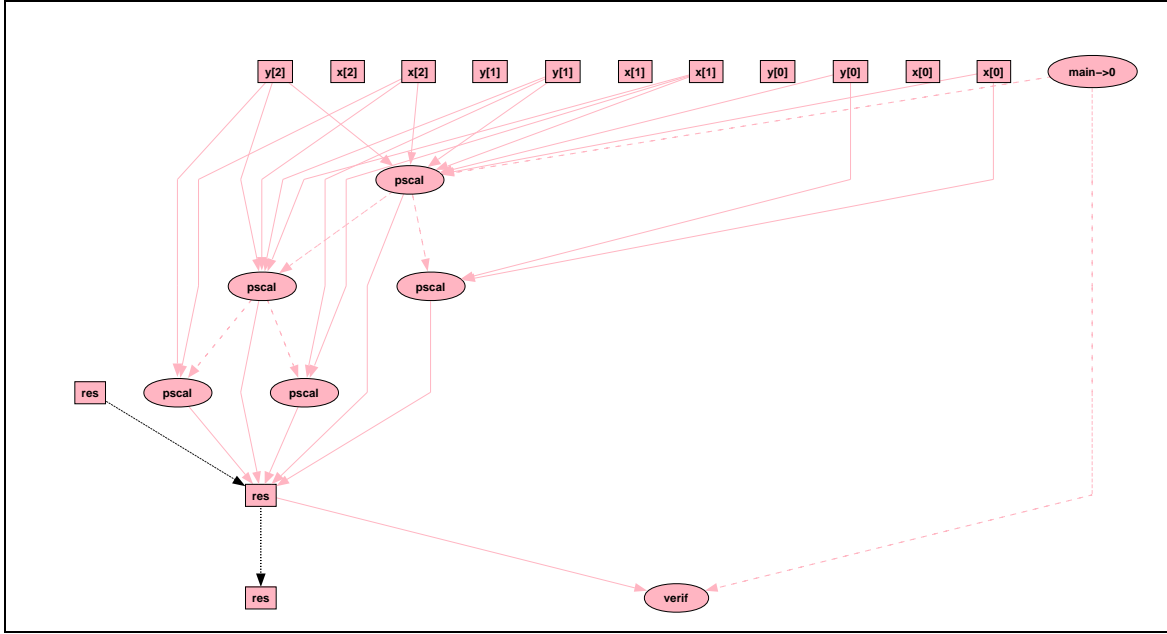

Figure 7: Execution graph corresponding to `pscal 3` execution.

## 9.4 Mandelbrot Set

This example intends to show the possible interaction between an ATHAPASCAN program and a X server. The following code results in a visualization of the Mandelbrot set on a X window. The algorithm is standard: the size of the image is split in four until a given threshold has been reached. The visualization is made during the computation, so that visualization threads have to execute on the X server site: a special scheduling policy is used for these threads.

## 10 Culminating Example: lifegame.cpp

The lifegame program was developed to provide a visualization of the asynchronous task execution performed by ATHAPASCAN. This program serves as an example for most of the concepts covered in this manual: passing and declaration of Shared data, Forking user-defined structures, the communicability of user-defined classes, and the internal scheduling of tasks by ATHAPASCAN.

The program as a whole can be divided into two parts: the simulation (lifegame.cpp, Message.cpp, Message.h) and the visualization (SappeJuggler.cpp, SappeJuggler.h, NJSocket.cpp, NJSocket.h, GOLApp.cpp, GOLApp.h). The simulation, in particular lifegame.cpp, uses ATHAPASCAN to parallelize the code. The Message class defined by the other two files sends the information needed for the visualization through the sockets it creates. The visualization portion of this project contains no parallel code, and is only used for receiving the messages sent by Message.cpp and generating a graphic output with OpenGL from the information received.

Lifegame.cpp creates a matrix of cells characterized by a boolean state, an integer time, and two integer coordinates: x, y (as defined in the cell\_state class). Given the state of the current cell and the current state of the cells surrounding it, the program calculates a new state for the current cell, updates the time variable, and sends this information as a message through a socket to visualization. The visualization receives this message and displays the matrix of cells. Each cell is displayed with a color corresponding to the time at which the cell was updated and the information sent.

When running this program in ATHAPASCAN's different modes (except sequential) the asynchronous task execution is clearly displayed by the color variance from cell to cell.

## 11 Frequently Asked Questions

This section contains a list of frequently asked questions about ATHAPASCAN (and some attempts at answering ;-)). Please feel free to send us any questions that would enable us to enlarge this section.

---

**Q:** On which systems do ATHAPASCAN run ?

**A:** Currently ATHAPASCAN has been tested on:

- IBM-SPx running aix-4.2 using LAM-MPI or a dedicated switch with
  - xlc 4.2 C++ compiler
- Sparc or Intel multiprocessor and network of workstations using LAM-MPI with
  - cc 4.2 C++ compiler

Athapascal-0 is currently supported on:

- AIX 3.2.5 and IBM/MPI-F, IBM SP with AIX 4.2 and IBM/MPI
  - DEC/Alpha with OSF/1 4.0 and LAM/MPI 6.1
  - HP-9000 with HP-UX 10.20 and LAM/MPI 6.1
  - SGI/MIPS with IRIX 6.3 and LAM/MPI 6.1, SGI/MIPS with IRIX 6.4 and SGI/MPI-3.1
  - Sparc or Intel with Solaris 2.5 and LAM/MPI 6.3
  - Intel with Linux 2.0.25, MIT threads 1.60.6 and LAM/MPI 6.3
- 

**Q:** How do I get a copy of ATHAPASCAN?

**Q:** Where can I comment about ATHAPASCAN?

**Q:** How do I get up-to-date information?

**A:** There is a web page dealing with ATHAPASCAN at <http://www-apache.imag.fr>. The ATHAPASCAN distribution, the manual (the document you are reading) and some other related papers are also available from this web page.

---

**Q:** The compilation failed: A1\_MAKEFILE not known! What do I do?

**A:** Check to see if you properly set up your environment by sourcing the appropriate setup file (the ones for Athapascal-0 and ATHAPASCAN).

---

**Q:** The option `-a1_trace_file` has no effect at execution! Why could this be?

**A:** Make sure you are using a program compiled with an appropriate ATHAPASCAN library (one compiled to generate dynamic graph visualization information).

---

**Q:** An ATHAPASCAN internal error occurs at execution! What can I do to correct this error?

**A:** If you are using MPI-LAM, please clean-up and reboot LAM before executing your ATHAPASCAN program. If the problem persists, please follow the instructions on the ATHAPASCAN webpage.

---

**Q:** The compiler doesn't find a task corresponding to my `a1::Fork` instruction. Why could this be?

**A:** Make sure that all the shared modes and rights are compatible.

**A:** Make sure the procedure does not have too many arguments. If so, recompile your library after having increased the authorized number of parameters at configuration (option `nbp` of `configure` script).

---

**Q:** I have tried all the previous suggestions and I still have some errors. What shall I do?

**A:** Send an e-mail to `Jean-Louis.Roch@imag.fr` stating your problem.
